A time-domain control signal detection technique for OFDM

Saheed A. Adegbite^{*†}, Scott G. McMeekin and Brian G. Stewart[†]

Abstract

Transmission of system-critical control information plays a key role in efficient management of limited wireless network resources and successful reception of payload data information. This paper uses an orthogonal frequency division multiplexing (OFDM) architecture to investigate the detection performance of a time-domain approach used to detect deterministic control signalling information. It considers a type of control information chosen from a finite set of information, which is known at both transmitting and receiving wireless terminals. Unlike the maximum likelihood (ML) estimation method, which is often used, the time-domain detection technique requires no channel estimation and no pilots as it uses a form of time-domain correlation as the means of detection. Results show that when compared with the ML method, the time-domain approach improves detection performance even in the presence of synchronisation error caused by carrier frequency offset.

Keywords: Carrier frequency offset (CFO), Channel estimation, Selective control information, Maximum likelihood (ML), Orthogonal frequency division multiplexing (OFDM), Time-domain correlation

1 Introduction

Efficient management of wireless network resources is essential in wireless communication systems. In most wireless systems, the management and allocation of system resources is usually coordinated through the use of some control signalling information [1]. Such control information carries important signalling information from a transmitting device (a base station) to a receiving terminal (a mobile station). In general, control information carries system-critical information about network configuration in order to enable successful reception of payload data and to facilitate efficient management of limited network resources [1–3]. To this end, the receiver must be able to successfully determine the transmitted control information for subsequent use during decoding of the payload data.

In wireless systems, the transmitted information usually consists of two components: control information and payload user data. The control information may be chosen from a finite set of known and pre-determined candidate information and can also be the same for multiple users.

Unlike the control information, the payload (user data) is randomly generated at the transmitter and it is usually different for each user. In terms of data recovery, detection of control signalling information is entirely different from the decoding procedures of payload user data information. In the literature, payload user-data information is normally recovered through what is generally considered as one-tap equalization (symbol-by-symbol) decoding where each subcarrier symbol is independently processed during data decoding [4–6]. On the other hand, a block-level detection is the most appropriate decoding approach for control information, particularly, selective control information (SCI) [7], which is considered in this paper. In a block-level decoding procedure, it is usually assumed that the SCI is represented by a group of subcarriers, which is chosen from a fixed number of pre-encoded sets of possible SCI (known at both transmitting and receiving terminals), as described in [7–10]. Therefore, at the receiver, the received group of subcarriers used to represent the SCI is collectively used during decoding [7]. For instance, a form of SCI can be used to represent the type of modulation scheme of payload user-data information. As an example, using the well-known quadrature

amplitude modulation (QAM) scheme, payload information may be modulated using 4-QAM, 16-QAM, 64-QAM or even 256-QAM. To recover the payload information, the receiver must first determine the type of modulation scheme. This can be achieved by encoding each possible type of modulation with a pre-coded information on a number of subcarrier to facilitate subsequent recovery through some form of block-level decoding.

Using a baseband orthogonal frequency division multiplexing (OFDM) architecture, this paper studies block-level detection of SCI. An OFDM architecture is considered because it is the adopted physical layer technology in several high-speed wireless systems such as Long-Term Evolution (LTE) [11–13]. Another example of SCI used within LTE systems is the control format indicator (CFI), which carries key system information that enables each user equipment (UE) to correctly decode the main control information within the LTE physical downlink control channel [1]. A detailed description of CFI and other forms of LTE control information can be found in [14].

To recover transmitted SCI, a maximum likelihood (ML) criterion is often used as the standard detection approach [7–10]. Unfortunately, the ML estimation scheme normally requires some form of channel mitigation through the use of, for example, pilot-assisted channel estimation in order to improve decoding performance [8]. As a consequence, transmission of additional system resources in the form of pilot or training signals is required to determine the channel response. However, to improve channel estimation, particularly in severe fading channel environments, a large number of pilot signals is required, which reduces the overall spectral efficiency [15].

To address the practical challenges associated with the ML-based receiver, this paper investigates the use of a time-domain approach for the recovery of SCI. The time-domain detection technique uses a decision rule that is derived from a time-domain correlation between the transmitted and received SCI, and as a consequence, eliminates the need for channel estimation at the receiver. Using the block error rate (BLER) performance metric, simulations evaluate the detection performance of the ML and the time-domain estimation methods in the presence of synchronisation error due to carrier frequency offset (CFO). Note that no CFO compensation is performed in this paper. Examples of recent studies on CFO and inter-carrier interference (ICI) (Inter-carrier interference) compensation are presented in [16] and [17].

The paper is structured as follows. Section 2 outlines the considered baseband OFDM architecture and describes an ML-based receiver to recover the transmitted SCI. Section 3 describes the implementation of the time-domain detection technique. Section 4 presents the

simulation results and related discussions on the BLER performance of the two considered methods. Finally, Section 5 highlights the main contributions of the paper.

2 System model

This section describes the baseband OFDM architecture used for the investigations within this paper. It also gives an overview of the ML-based receiver studied in, for example, [7].

2.1 Transmitter

Let X be an OFDM sequence of length N_v , which is the raw input for the inverse fast Fourier transform (IFFT) stage before zero padding. Then, for $0 \leq k \leq N_v - 1$ where k represent a subcarrier index, X is written as

$$X = [X[0] \ X[1] \ X[k] \ \dots \ X[N_v - 1]]. \quad (1)$$

For simplicity, it is assumed X consists of randomly generated data, X_d of size N_d , a pilot sequence, X_p of size N_p , and an SCI vector, X_c of size N_c , such that $N_v = N_p + N_c + N_d$. Each element of X is mapped to a subcarrier symbol $X[k]$ through, for example, a subcarrier mapping scheme described as follows:

1. First, each pilot subcarrier symbol is inserted at every L subcarrier indices where L defines the pilot spacing. In this paper, L is set to 6, so that the pilots are mapped to, for example, $k = \{0, 6, 12, 18, \dots\}$, as specified for LTE systems [18].
2. Given that $X_c \in \mathcal{S}$ where \mathcal{S} consists of U candidate sequence vectors where \mathcal{S} is considered to be deterministic and is known at both transmitter and the receiver. For $1 \leq u \leq U$, each sequence vector in \mathcal{S} is denoted by S_u , i.e.,

$$\mathcal{S} = \{S_1, S_2, S_u \dots S_U\}. \quad (2)$$

For an arbitrary index c where $0 \leq c \leq N_c - 1$, each SCI S_u is

$$S_u = [S_u[0], S_u[1], S_u[c] \dots S_u[N_c - 1]]$$

As in most practical applications, each $S_u[c]$ is QPSK modulated. Hence, the magnitude of $S_u[c]$ is 1. Let \bar{u} define the u index of the transmitted sequence chosen from \mathcal{S} . Hence,

$$X_c = S_{\bar{u}} \text{ where } S_{\bar{u}} \in \mathcal{S}. \quad (3)$$

Each element of X_c is mapped to the next available N_c subcarriers in X . It can be noted from (3) that transmitted SCI can be known using the index \bar{u} .

- Finally, the remaining N_d un-allocated subcarriers in \mathbf{X} are assigned to each element of randomly generated modulated data \mathbf{X}_d .

Figure 1 shows the block diagram representation of a baseband OFDM transmitter architecture used for SCI transmission. It can be noted that this architecture inserts some pilots to enable channel estimation as required by the ML estimation method. However, as will be shown later, these pilots are not used and remain passive in the time-domain detection method.

As in the standard OFDM transmitter, the OFDM sequence, \mathbf{X} is transformed into a time-domain OFDM signal, \mathbf{x} of length N , using an N -point IFFT where $N > N_v$, i.e. zero padding is applied during IFFT where $N - N_v$ zeros are appended after the first N_v subcarriers. For $0 \leq n \leq N - 1$, each individual sample $x[n]$ in \mathbf{x} is obtained through

$$\begin{aligned} x[n] &= \frac{1}{N} \sum_{k=0}^{N_v-1} X[k] \exp(j2\pi nk/N) \\ &= \text{IFFT}_{N\text{-point}} \{X\}, \end{aligned} \quad (4)$$

where $\text{IFFT}\{\cdot\}$ denotes an IFFT function.

Similarly, as in the standard OFDM described in, for example, [19], the length of the OFDM signal \mathbf{x} is further extended by a cyclic prefix (CP) so as to mitigate channel fading and inter-symbol interference (ISI) [20].

2.2 Receiver

At the receiver, CP samples are first removed. After the fast Fourier transform (FFT) stage at the receiver, the frequency domain representation of the received OFDM symbol \mathbf{Y} is given as [21]

$$\mathbf{Y} = \mathbf{H}\mathbf{X} + \mathbf{V}. \quad (5)$$

Note that \mathbf{H} and \mathbf{V} in (5) are, respectively, the frequency domain representation of the complex-valued channel

frequency response and additive white Gaussian noise (AWGN). Hence, each subcarrier $Y[k]$ in \mathbf{Y} is written as

$$Y[k] = H[k]X[k] + V[k]. \quad (6)$$

Let f_0 and Δf , respectively, represent the frequency offset and the OFDM subcarrier spacing (both in Hertz). Then, a normalised CFO, ε is expressed by [21]

$$\varepsilon = f_0 / \Delta f. \quad (7)$$

In the presence of CFO, \mathbf{Y} is represented by [21]

$$\mathbf{Y} = \mathbf{G}(\varepsilon)\mathbf{H}\mathbf{X} + \mathbf{V}, \quad (8)$$

where

$$\mathbf{G}(\varepsilon) = \mathbf{F}\mathbf{C}[\varepsilon]\mathbf{F}^H. \quad (9)$$

The term \mathbf{F} in (9) represents an $N \times N$ matrix with each element F_{nk} given by [22]

$$F_{nk} = \exp(-j2\pi nk/N) / \sqrt{N}, \quad (10)$$

and $\mathbf{C}[\varepsilon]$ in (9) is a diagonal matrix expressed by [21]

$$\mathbf{C}[\varepsilon] = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & \exp(j2\pi\varepsilon/N) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \exp(j2\pi\varepsilon(N-1)/N) \end{pmatrix}. \quad (11)$$

Similar to (5), the received SCI sequence vector, \mathbf{Y}_c , is given by

$$\mathbf{Y}_c = \mathbf{H}_c\mathbf{X}_c + \mathbf{V}_c, \quad (12)$$

where \mathbf{H}_c and \mathbf{V}_c , respectively, represent the sub-channel gains and AWGN components associated with the received selective sequence \mathbf{Y}_c . Similarly, the received pilot, \mathbf{Y}_p , is given by

$$\mathbf{Y}_p = \mathbf{H}_p\mathbf{X}_p + \mathbf{V}_p, \quad (13)$$

where H_p and V_p , respectively, represent the sub-channel gain and AWGN components within the received pilot sequence Y_p .

Thus, to recover X_c , the receiver must determine an estimate of \bar{u} since the transmitted SCI is chosen from a deterministic set, \mathcal{S} , and is considered to be known at the receiver.

2.3 ML-based detection

Let \hat{u} denote an estimate of \bar{u} . Then, using the ML estimation criterion, \hat{u} is obtained from [7]

$$\hat{u} = \arg \min_u \|Y_c - \hat{H}_c S_u\|^2. \quad (14)$$

The term \hat{H}_c represents the sub-channel estimates (associated with the received SCI). In this paper, \hat{H}_c is obtained from a linear interpolation between the least squares (LS) sub-channel pilot estimates, \hat{H}_p , where

$$\hat{H}_p = Y_p / X_p. \quad (15)$$

In (14), it can be seen that the ML estimation criterion is a form of Euclidean distance minimisation function. Again, from (14), it can be noted that the detection performance of the ML estimation method depends mainly on the channel estimate \hat{H}_c . Hence, poor channel estimation is expected to result in erroneous estimate of \hat{u} . This is the main drawback of the ML estimation method.

3 The proposed method

In a classical channel estimation scheme such as minimum mean square error (MMSE), some form of correlation is often applied to determine the channel response [4, 23].

In addition, studies from, for example, [24] and [25] suggest that a time-domain approach is more robust against severe ISI compared with the frequency-domain method of channel equalization. This was partly due to the partial elimination of the channel tap with the most energy in the time-domain [26]. These principles form the basis behind the use of the time-domain estimation technique considered in this paper.

In the time-domain detection scheme, some form of correlation function is derived from the 'correlation' of Y_c with each of the candidate sequences within the set \mathcal{S} since \mathcal{S} is deterministic and known at both transmitting and receiving terminals. The rationale for the use of a time-domain correlation follows a general principle of deterministic signal correlation, which suggests that similar to the auto-correlation principle, there exists an inherent correlation between Y_c and X_c , in the presence of limited noise levels, since X_c is deterministic and chosen from, for example, a known set \mathcal{S} .

Figure 2 shows the block diagram representation of a baseband OFDM receiver for SCI detection based on the ML and the time-domain estimation methods. As previously stated, it can be noted from Fig. 2 that the time-domain method requires no channel estimation. The time-domain decision rule is now described through the use of the well-known discrete correlation theorem (DCT) (Discrete correlation theorem).

3.1 Time-domain decision criterion

Using the DCT, a correlation function (CORR) of two arbitrary time-domain signals c_1 and c_2 (of the same size) is obtained from [27]

$$\text{CORR}\{c_1, c_2\} = \text{IFFT}\{C_1 \times C_2^*\}, \quad (16)$$

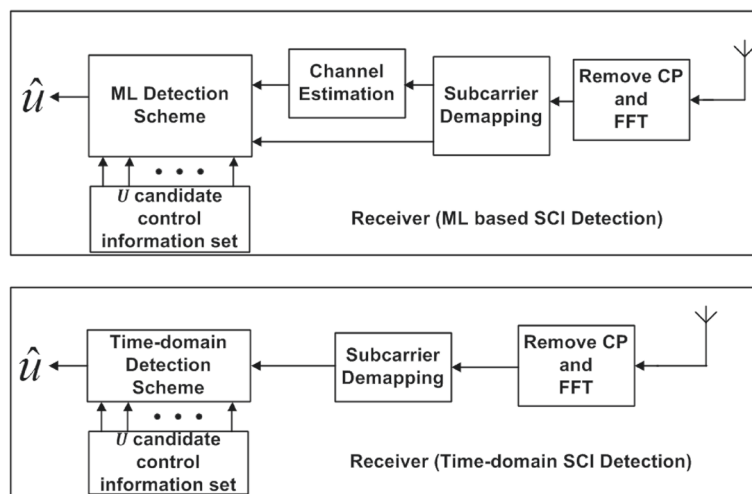

Fig. 2 A block diagram representation of a baseband OFDM receiver for SCI detection using ML and the time-domain method

where $*$ represents the complex conjugation and C_1 and C_2 are, respectively, the frequency domain representations of c_1 and c_2 , i.e.

$$\begin{aligned} C_1 &= \text{FFT}\{c_1\} \\ C_2 &= \text{FFT}\{c_2\}, \end{aligned} \quad (17)$$

where $\text{FFT}\{\cdot\}$ denotes FFT function.

Similar to the definition in (16), a term Z_u is obtained from direct multiplication of Y_c with the complex conjugate of each S_u . Thus, Z_u is derived from

$$\begin{aligned} Z_u &= Y_c \times S_u^* \\ &= (H_c X_c + V_c) \times S_u^* \\ &= (H_c X_c S_u^* + V_c S_u^*) \\ &= \left(\frac{H_c X_c}{S_u} \right) + \left(\frac{V_c}{S_u} \right) \\ &= \left(\frac{H_c X_c}{S_u} \right) + V'_{c,u}. \end{aligned} \quad (18)$$

For $0 \leq c \leq N_c - 1$, Z_u may be represented as

$$Z_u = [Z_u[0], Z_u[1], Z_u[c], \dots, Z_u[N_c - 1]]. \quad (19)$$

Alternatively, Z_u can also be written as

$$Z_u = \begin{cases} H_c + V'_{c,u}, & u = \bar{u} \ (X_c = S_u) \\ H_c X_c S_u^* + V'_{c,u}, & \text{otherwise.} \end{cases} \quad (20)$$

By omitting the noise terms in (20) for simplicity (at high signal-to-noise ratio (SNR)), the expression for Z_u in (20) is reduced to

$$Z_u \approx \begin{cases} H_c, & u = \bar{u} \\ H_c X_c S_u^*, & \text{otherwise,} \end{cases} \quad (21)$$

where $X_c S_u^*$ is a complex-valued number with unity magnitude since each S_u is assumed to have the same magnitude.

From the expression in (20), it can be seen that the same channel term H_c and identical noise term $V'_{c,u}$ is present in both $Z_{u=\bar{u}}$ and $Z_{u \neq \bar{u}}$ terms when $u = \bar{u}$ and $u \neq \bar{u}$, respectively. Hence, the term H_c is considered (for decoding purpose) as a gain effect. Thus, without loss of generality, the main difference between each value of $Z_{u=\bar{u}}$ and $Z_{u \neq \bar{u}}$ can be written as

$$Z_u[c] \approx \begin{cases} 1, & u = \bar{u} \\ X_c S_u^*, & \text{otherwise.} \end{cases} \quad (22)$$

Similar to (16), a real-valued time-domain correlation function, W_u is computed from $Z_u[c]$ using a \mathcal{W} -point IFFT where \mathcal{W} must be a power of 2 and $\mathcal{W} \geq N_c$, i.e. $\mathcal{W} = N_c$ if N_c is a power of 2; otherwise, $\mathcal{W} > N_c$.

For $0 \leq w \leq \mathcal{W} - 1$, W_u is written as

$$W_u = [W_u[0], W_u[1], W_u[w], \dots, W_u[\mathcal{W} - 1]], \quad (23)$$

where

$$W_u = \left| \text{IFFT}_{\mathcal{W}\text{-point}} \{Z_u\} \right|, \quad (24)$$

where $|\cdot|$ computes the magnitude of a complex-valued variable. It should be noted that in this paper, the IFFT operation in (24) performs no zero padding since each considered value of N_c is a power of 2, i.e. the $\mathcal{W} = N_c$. However, in cases (not shown in this paper) where N_c is not a power of 2, zero padding can be applied accordingly to reduce computational complexity and with no expected degradation in performance.

From the approximation of $Z_{\bar{u}}$ in (22), the IFFT of $Z_{\bar{u}}$ yields an impulse function. Hence, the value of $W_{\bar{u}}[w]$ (derived from $Z_{\bar{u}}$) is approximated as

$$W_{\bar{u}}[w] = \begin{cases} 1, & w = 0 \\ 0, & 1 \leq w \leq N_c - 1. \end{cases} \quad (25)$$

Otherwise, $W_u[w] > 0$ when $u \neq \bar{u}$.

Using the approximation in (25), it can be noted that the mean value of $W_{\bar{u}}[w]$, i.e. $E\{W_{\bar{u}}[w]\}$, is

$$\begin{aligned} E\{W_{\bar{u}}[w]\} &= \frac{1}{\mathcal{W}} \sum_{w=0}^{\mathcal{W}-1} W_{\bar{u}}[w] \\ &\approx 1/\mathcal{W} \end{aligned} \quad (26)$$

where E is the expectation function.

Similarly, from the definition in (25), $E\{W_{u \neq \bar{u}}[w]\}$ is expected to be larger than $E\{W_{\bar{u}}[w]\}$ because the corresponding values of $W_{u \neq \bar{u}}[w]$ are non-zero. Hence,

$$E\{W_{\bar{u}}[w]\} \ll E\{W_{u \neq \bar{u}}[w]\}. \quad (27)$$

Thus, in the presence of channel fading term H_c , the expression in (27) is still valid since the resulting time-domain functions $W_{\bar{u}}$ and $W_{u \neq \bar{u}}$ are both affected by the same channel component.

The expression in (27) therefore implies that an estimate of \bar{u} corresponds to the u -index of the time-domain function with the minimum mean value amongst all U

Table 1 Power delay profile of the EVA multipath fading channel

Channel parameters	Tap 1	Tap 2	Tap 3	Tap 4	Tap 5	Tap 6	Tap 7	Tap 8	Tap 9
Path delay, ns	0	30	150	310	370	710	1090	1730	2510
Power, dB	0.0	-1.5	-1.4	-3.6	-0.6	-9.1	-7.0	-12.0	-16.9

time-domain functions. Hence, it can be said that the time-domain decision criterion minimises the mean value of the time-domain correlation function obtained from (24). Thus, the time-domain detection rule is defined as

$$\hat{u} = \arg \min_u E \{ W_u[w] \}. \quad (28)$$

From the expressions in (18) to (28), it can be noted that no channel estimation and no pilots are required in the time-domain method because the time-domain correlation inherently facilitates detection even in the presence of a fading channel [28]. However, as will be shown in the next section, one of the main limiting factors for the proposed detection method is the inaccuracy of the time-domain decision metric for small values of N_c .

4 Simulation results

This section presents the comparison of the detection performance of the two considered detection methods using the BLER metric.

4.0.1 Computing BLER

The BLER is not the same as the well-known bit error rate (BER) metric. In the case of BER, individual bit errors are considered. However, to compute the BLER, an error count between the actual value \bar{u} that corresponds to the selected sequence X_c and its estimate \hat{u} , obtained from the ML or the time-domain detection scheme, is evaluated. Hence, an erroneous block is when $\bar{u} \neq \hat{u}$; otherwise, there is a successful detection. For each SNR level, the BLER is evaluated as

$$\text{BLER} = \frac{1}{N_{\text{BLK}}} \sum_{i=1}^{N_{\text{BLK}}} R_i. \quad (29)$$

For $1 \leq i \leq N_{\text{BLK}}$ where N_{BLK} is the number of OFDM symbol blocks (for a given SNR level), R_i is computed from

$$R_i = \begin{cases} 1 & \text{if } \bar{u} \neq \hat{u} \\ 0 & \text{otherwise.} \end{cases} \quad (30)$$

4.0.2 Simulation setup

OFDM simulation considers transmission over a frequency-selective Rayleigh fading channel known as the extended vehicular type A (EVA), with a root mean square

(RMS) delay spread, τ_{rms} , of 357 ns [29]. Table 1 shows the power delay profile of the EVA channel [30]. Simulations use parameter values outlined in Table 2 and are carried out using MATLAB. To further understand the detection performance of each considered detection scheme, simulations also evaluate the BLER performance in the absence of a fading channel, i.e. the presence of AWGN only.

The BLER performance of the two considered methods is investigated as a function of ε for each value of N_c . Note that since each chosen value of N_c is a power of 2, then $\mathcal{W} = N_c$. It should also be noted that for the ML scheme, simulations implement the pilot-assisted channel estimation procedures previously outlined in (15) and linear channel interpolation is used to obtain \hat{H}_c .

4.0.3 Numerical results and discussions

In the presence of only AWGN, Fig. 3a–d shows the BLER comparisons between the two considered detection methods with N_c set to 8, 16, 32 and 64, respectively. Results in Fig. 3a show that for a small block size ($N_c = 8$), the ML scheme produces improved BLER performance compared with the time-domain method. However, results in Fig. 3b–d suggest that the detection performance of the time-domain estimation method is improved as N_c is further increased. Results in Fig. 3 also demonstrate that in this case (i.e. with no fading channel effects), the BLER performance of the ML scheme is relatively the same even when N_c is increased. In summary, results in Fig. 3 suggest that (1) the time-domain method is robust

Table 2 Simulation parameters

Parameters	Values
OFDM subcarrier spacing	15 KHz
Sampling frequency	3.84 MHz
Pilot spacing, L	6 (i.e. $N_p = 30$)
IFFT/FFT size, N	256
OFDM sequence size, N_{sub}	180
N_c	8, 16, 32 and 64
Guard interval (GI)	5.21 μs
Modulation	QPSK
U	4
Number of OFDM symbol blocks, N_{BLK}	50,000
Normalised CFO, ε	0, 0.01 and 0.05

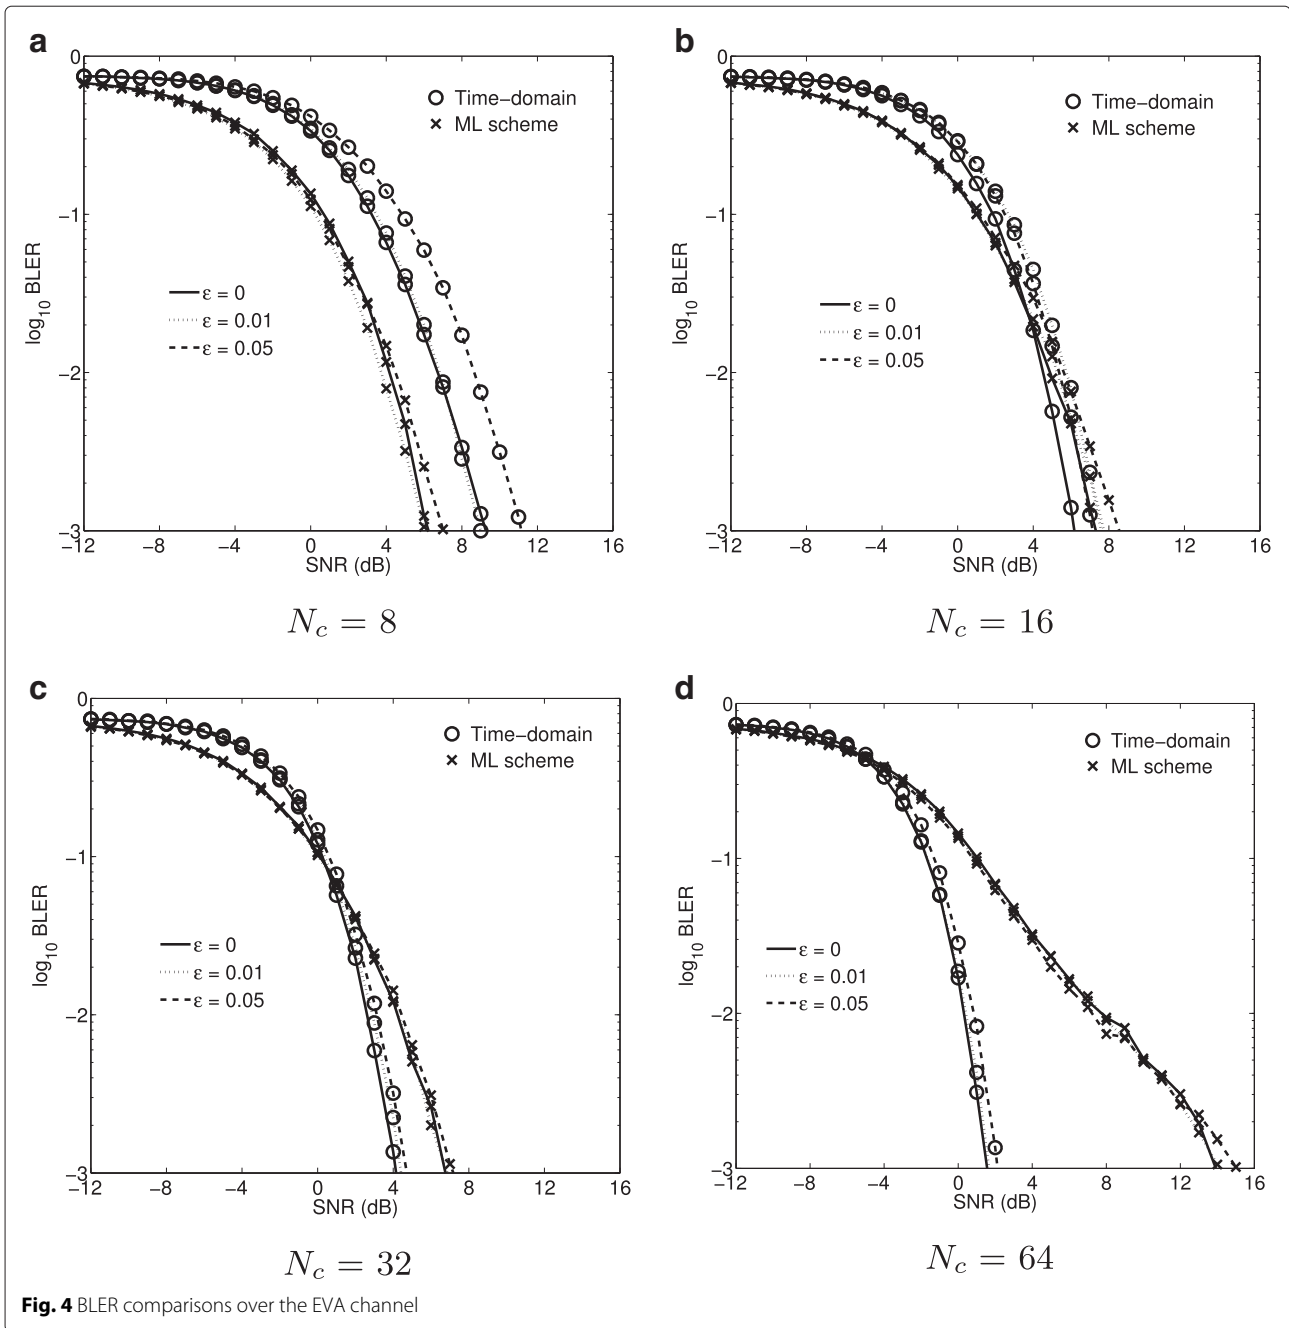

Fig. 3 BLER comparisons in the absence of channel fading

against synchronisation error due to CFO; (2) the detection performance of the time-domain method can be improved with larger values of N_c ; and (3) in the absence of channel fading, the detection performance of the ML estimation method is nearly the same for all the considered values of N_c . Figure 4a–d shows BLER comparisons when transmission is over the EVA fading channel. Similar to the previous results in Fig. 3a, results in Fig. 4a, b show that the ML estimation method outperforms the time-domain method when $N_c = 8$ and 16. However, as N_c is

further increased, the detection performance of the time-domain detection scheme is further improved compared with the ML detection approach, as shown in Fig. 4c, d. This is because as N_c is further increased, statistical evaluation of the applied time-domain decision metric is more accurate, and as a result, its detection performance is improved compared with the ML scheme. Results further show that in the presence of frequency-selective channel fading effects, the ML scheme only produces minimal improvement in detection performance as N_c is

increased. This is because with increased N_c , more subcarriers may have experienced severe (deep) channel fading, which can lead to noise enhancement and hence poor detection.

From the results in Figs. 3 and 4, Table 3 shows the estimated SNR required to achieve, for example, a BLER level of 1% (i.e. $\text{BLER} = 10^{-2}$). From Table 3, it can be noted that the time-domain detection method requires relatively smaller SNR levels compared with the ML scheme when

$N_c \geq 16$ (in AWGN) and $N_c \geq 32$ (in EVA). For instance, in the presence of channel fading and when $\epsilon = 0.05$, the time-domain estimation method requires around 1.3 (when $N_c = 32$) and 6.4 dB (when $N_c = 64$) less SNR to achieve the same BLER target (of 1%) as the ML scheme. The low SNR requirement of the time-domain method therefore makes it a potential and practical technique for detecting deterministic control signals in OFDM systems, particularly when N_c is large.

Table 3 Estimated SNR (dB) requirements of the ML scheme and the time-domain method at BLER = 1 %

Channel	Normalised CFO, ε	Detection schemes	SNR (dB) @ BLER = 1 %			
			$N_c = 8$	$N_c = 16$	$N_c = 32$	$N_c = 64$
AWGN	$\varepsilon = 0$	ML	2.2	1.9	1.4	0.3
		Time-domain	3.9	0.5	-2.5	-5.1
	$\varepsilon = 0.01$	ML	2.7	1.8	1.1	0.1

		Time-domain	6.8	4.7	2.7	0.5
	$\varepsilon = 0.01$	ML	3.8	5.3	4.3	7.7
		Time-domain	6.9	5.8	2.9	0.6
	$\varepsilon = 0.05$	ML	4.6	5.7	4.5	7.3
		Time-domain	8.7	5.5	3.2	0.9

5 Conclusions

This paper considered the detection of deterministic SCI in a baseband OFDM architecture. The detection performance of a time-domain correlation method is investigated and compared against the conventional ML estimation method. A key benefit of the time-domain estimation method is that it requires no channel estimation at the receiver. The detection performance of the time-domain estimation method is found to be largely dependent on the value of N_c , which represents the size of the SCI. In the presence of channel fading and CFO, the time-domain method achieves an improved detection performance over the ML approach when $N_c \geq 32$. Therefore, the time-domain method is a viable and a potential detection scheme for detecting deterministic control information often encountered in practical wireless OFDM systems.

Abbreviations

AWGN, additive white Gaussian noise; BER, bit error rate; BLER, block error rate; CFI, control format indicator; CFO, carrier frequency offset; CP, cyclic prefix; EVA, extended vehicular type A; FFT, fast Fourier transform; IFFT, inverse fast Fourier transform; ISI, inter-symbol interference; LTE, Long-Term Evolution; ML, maximum likelihood; MMSE, minimum mean square error; OFDM, orthogonal frequency division multiplexing; RMS, root mean square; SCI, selective control information; SNR, signal-to-noise ratio; QAM, quadrature amplitude modulation

Competing interests

The authors declare that they have no competing interests.
